

Feasibility Study of Short Takeoff and Landing Urban Air Mobility Vehicles using Geometric Programming

Chris Courtin*, Michael Burton†, Patrick Butler‡, Alison Yu§, Parker Vascik ¶, John Hansman||

Massachusetts Institute of Technology, Cambridge, 02139, USA

The feasibility of an Urban Air Mobility (UAM) system that features electric Extremely Short Takeoff and Landing (ESTOL) vehicles is investigated. An overview is given of the system constraints that must be incorporated into the design of the vehicle. The system-wide advantages and limitations of ESTOL aircraft are discussed, for both near- and far-term system implementations. A detailed vehicle sizing model is developed using geometric programming, a robust optimization framework. This model is used to determine feasible boundaries on required runway size, vehicle range, and the sensitivity of the vehicle design to high-level mission parameters such as speed and number of passengers. Key unique drivers of the vehicle design are identified. The impact of distributed electric propulsion (DEP) is assessed. Performance relative to a comparable Vertical Takeoff and Landing (VTOL) vehicle is analyzed, both with currently available technology and forecasted future technology. The infrastructure requirements (runway size, approach paths, etc.) needed to support ESTOL operations are assessed according to current regulations. Two major urban areas (Boston and Los Angeles) are presented as case studies to show where this infrastructure could be feasibly located. Key challenges and risks to implementation are discussed.

Nomenclature

A	takeoff helper variable	P_{spec}	specific motor power
AR	wing aspect ratio	Re	Reynolds number
b	wing span	S	wing area
B	takeoff helper variable	S_{land}	landing ground roll
c	wing chord	S_{runway}	runway distance
C_D	drag coefficient	S_{TO}	take off ground roll
CDA	area drag coefficient	S_{spar}	spar section modulus
C_{Dg}	ground drag coefficient	t	time
c_{dp}	wing profile drag coefficient	T	thrust
C_L	lift coefficient	V	speed
C_{Lg}	ground lift coefficient	V_{stall}	stall speed
$C_{L\max}$	max lift coefficient	W_{batt}	battery weight
D	drag	W_{fadd}	additional wing weight
e	span efficiency	W_{motor}	motor weight
f_{struct}	fractional structural weight	W_{MTO}	max take off weight
g	gravitational constant	W_{pay}	payload weight
L	lift	W_{skin}	wing skin weight
M_{root}	root moment stress	W_{spar}	wing spar weight
N	deceleration factor	W_{struct}	structural weight
$P_{\text{shaft-max}}$	max shaft power	W_{wing}	wing weight

I. Introduction

Urban Air Mobility (UAM) is a popular concept in aviation that proposes an aerial transportation network that bypasses the congested ground infrastructure surrounding major cities. It features a fleet of relatively small vehicles operating off a distributed network of takeoff and landing areas (TOLAs) located within dense urban centers. UAM concepts of some form or another have been around for at least the past fifty years; helicopters have been performing UAM-type missions since the 1960s and have sufficient performance capability to meet nearly all payload, speed, and range requirements of current proposed UAM mission profile. However, historical helicopter public transportation networks by and large did not succeed and do not exist today due to the high costs of helicopter operation, the high noise generation of these vehicles, and the poor safety record of these aircraft. Recently, advances in electric vehicle propulsion and key subsystem technologies have created the potential for new vehicle configurations that may mitigate some of these systemic challenges. Additionally, the ride-sharing model that has been successful for ground transportation has the potential to further improve the economics of air vehicle operations through pooling and on-demand service. This has sparked renewed interest in the UAM concept and the development of UAM-specific vehicles by numerous legacy and emerging aircraft manufacturers.

The landscape of vehicles being proposed for UAM missions is incredibly diverse, and many vehicle configurations are being developed, including multicopters, tilt-rotors, and slowed rotors. While some utilize wing-borne lift for the cruise phase of flight, every vehicle proposed to date has Vertical Takeoff and Land (VTOL) capability. In almost all configurations, this is accomplished via a distributed electric propulsion (DEP) system of many small electric motor/propeller combinations. VTOL capability minimizes the amount of space the vehicle requires to take off, and minimizes susceptibility to crosswinds, while DEP increases system efficiency and safety. This is useful capability for operations in areas where space is at a premium, but imposes two significant penalties on the vehicle. The first is in performance; the weight of the high-power system needed to perform the vertical takeoff and landing limits the amount of payload these vehicles can carry, or the range at which they can carry it. This effect is especially pronounced for electric aircraft, where payload and range are already compromised by the poor specific energy of current battery technology relative to hydrocarbon fuels. The second, and more significant, penalty is that VTOL configurations increase the already substantial amount of risk associated with the UAM concept.

Any proposed UAM system is exposed to many sources of risk, such as local noise regulations, ATC capacity concerns, pilot or automation availability, infrastructure availability, and uncertain market demand. Of all the risk sources, one of the most significant is the ability to certify these new types of aircraft. This risk is so significant in part because historically certification of new aviation technologies is a slow and difficult process, and also because an inability to certify a vehicle would preclude UAM operations, at any scale.

In considering certification risk, it is important to differentiate between risk inherent in certifying a vehicle configuration, and risk inherent in certifying a vehicle flight control system. In many UAM proposals, advanced vehicle automation is seen as a key enabling technology for large-scale operations, while initial operations are expected to operate with a human pilot operating the aircraft [?]. To achieve that initial operational capability, vehicle automation or flight control systems must only be certified to the point where they allow a trained pilot to operate the vehicle. Certification of advanced autonomous systems is a separate risk category, and should not be confused the risk of certifying the vehicle configuration for traditional piloted operations.

Within the landscape of potential UAM configurations, DEP eVTOLs are by far the most common. While they differ substantial in the details, they all require three common features: 1) A flight stabilization system that controls vehicle attitude and lift during the vertical and translational phases of flight via differential thrust on the motors, 2) A power delivery system that supplies power from the batteries to the motors, and 3) a large battery to act as a store of electrical power.

For an electric VTOL (eVTOL) configuration to be certified, there must be a very small probability (10^{-7} - 10^{-8} [?]) of a catastrophic failure per flight hour. In practice, this means that all key vehicle failure modes must be effectively and robustly mitigated. Each of the three systems mentioned above constitutes a critical source of failure inherent in the DEP eVTOL configuration, especially if that failure occurs at

low altitudes. Any failure of the flight stabilization or the power delivery system, cannot be tolerated, as it would result in a loss of vehicle control. At high altitudes an airframe parachute is a possible mitigation but current ballistic recovery systems are only certified above 400ft AGL (or higher with no forward airspeed) [?]; immediately after takeoff and before landing they are not effective. The risk of a lithium polymer battery going into thermal runaway is another key risk. Thermal runaway occurs when a short circuit forms within the battery, causing an uncontrolled increase in temperature and pressure, which can trigger a chain reaction in neighboring cells. There are several ways a battery cell could go into thermal runaway; overcharging or over-discharging, mechanical damage, or an internal short circuit caused by a manufacturing defect [?]. While modern battery control systems can effectively prevent over-charging of the battery, mechanical damage and especially internal short circuits are hard to prevent with a high degree of certainty.

These failure modes are difficult to mitigate, especially in highly weight- and cost-sensitive vehicles. For flight-critical power delivery and flight stabilization systems, high levels of redundancy, such as found on commercial jetliners, are an acceptable means of certification, but this adds cost and difficult to the certification process. Current regulations also require that flight batteries are shown to be safe in the event of a thermal runaway [?]. This regulation is normally complied with through battery containment, which adds potential significant weight to the battery system [?].

The intention here is not to argue that it is impossible to certify an eVTOL aircraft, but rather to emphasize that it will be a difficult, expensive process which has a good chance of further penalizing already marginal vehicle performance. Certification of any new aviation technology is hard, and combining multiple new technologies with novel vehicle configurations compounds the difficult. Since certification currently is a prerequisite for any commercial flight activity [?], this process will pace any proposed UAM network implementation.

One way of reducing this key risk factor is to use a lower-risk vehicle architecture that minimizes the amount of new technology required. Short takeoff and land (STOL) aircraft are fixed-wing aircraft design primarily for short-field operations. By utilizing the wing throughout all phases of flight, STOL aircraft also have performance advantages compared to VTOL aircraft of similar payload capacity, since they need much less power (and hence have much lighter power systems). Since they are inherently stable, there is no need for electrically actuated controls or a flight stabilization system, eliminating the need for complex control architecture and the associated redundant systems. If they are electrically powered, thermal runaway in the battery system is still a concern. However, STOL configurations are less sensitive to weight than VTOL configurations, potentially lessening the performance penalty associated with a battery containment system.

The clear downside of STOL aircraft is they require a runway of some length, which increases the infrastructure required to build a TOLA. In dense urban areas, availability of infrastructure is severely limited. If no runways can be placed in useful locations, then any advantages of STOL vehicles are immaterial. To realize those advantages, it must be possible to design an aircraft that can land on a runway short enough that there are a large number of potential locations in a dense urban area. Currently, it is not clear that this is possible.

The purpose of this paper is to assess the feasibility of an UAM system that features STOL aircraft, from both a vehicle and infrastructure perspective. The goal is to determine how short a runway a fixed-wing aircraft with modern technology can be designed to land on while still maintaining a useful operational capability, and how the runway length impacts the availability of potential locations in a dense urban area. As part of this work, previous literature concerning small aircraft transportation system design [?], [?], thin-haul transportation vehicles [?], [?], [?], VTOL aircraft [?], and STOL aircraft is considered [?], [?].

II. Vehicle Requirements Definition and Market Analysis

To perform a feasibility study of this new class of aircraft, the high-level vehicle requirements (range, speed, and payload) must be established, which arise from the projected use case of UAM vehicles. The clearest need for an urban air mobility system arises from the surface congestion problem that plague most major metropolitan areas. Large numbers of people travel into and out of the urban center every day, creating massive surface congestion that extends for miles outside of the city. To be an effective alternative to ground transportation, a UAM vehicle must have sufficient range to bypass likely surface congestion, and preferably to be located near the homes of the commuting population, as well as speed that offers significant time savings over an automobile. To estimate the range and speed requirements for a UAM vehicle, three representative

US cities were considered; Boston, Dallas, and Los Angeles. Figure 1 shows average commuting times in the area surrounding each city as reported by the 2011 US Census (top) [?] and representative traffic congestion during rush hour from Google Maps (bottom) [?]. It can be seen from these maps that a range of at least 50 nmi is required to bypass the surface congestion surrounding the city, and a range of 100nmi gives good access to the majority of the commuting population. For this reason, 100 nmi (plus required reserves) will be used as a baseline range requirement. A design cruise speed requirement of no less than 100kts will also be included. This is selected as a reasonable value that offers significant time savings over ground transportation (especially with traffic); the effects of increasing or decreasing this speed requirement will be assessed in detail in subsequent sections. The payload requirements for the vehicle are derived from

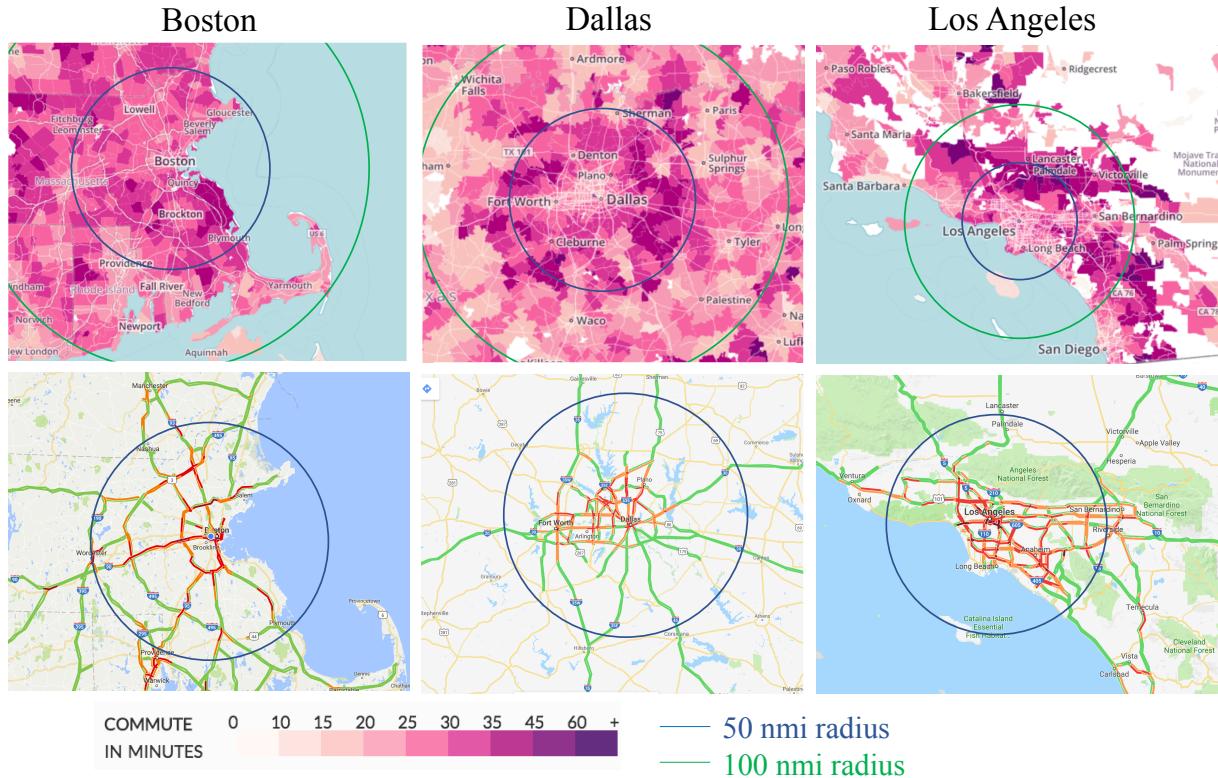

Figure 1: Surface congestion surrounding major metropolitan areas drives the need for urban air transportation

the need to carry both a pilot (in initial operations) as well as a sufficient number of passengers. Uber and others have shown there to be a potential market for vehicles carrying only a pilot and a single passenger, but that more passengers improves the economic viability of the concept [?]. This is especially true in early operations before widespread vehicle automation, where the number of pilots is likely to be limited by pilot availability, and the number of vehicle operations may be limited by ATC constraints. The number of passengers onboard is also expected to trade with vehicle size and hence required runway length. Therefore, for this study there is a minimum requirement of at least one pilot and one passenger, to provide a common baseline with VTOL concepts. A key goal is to determine how required runway length scales as the number of passengers are increased. The design mission for this feasibility study is summarized in Table ???. This is similar to the design missions proposed for other UAM vehicles [?], [?], [?].

In order for this concept to be viable (for any type of vehicle), there must be infrastructure available to support the takeoff and landing operations at both the origin and the destination. Initial operations would ideally take advantage of existing infrastructure where possible. Figure 2 shows the existing air transportation infrastructure around the same three cities. The top row shows existing public use airports, while the bottom row shows a close-up of the urban core that is the destination for most commuters. From this it can be seen that surrounding most cities there is a significant amount of existing small airports that are well

suited to UAM operations. However, in the urban core existing air infrastructure, for either VTOL or STOL aircraft, is very limited. Many existing helipads are also reserved for medical operations, so for both Dallas and Boston being able to use existing VTOL infrastructure does not offer a significant advantage over using existing STOL infrastructure (airports); in both cases, significant additional infrastructure development will be required to operate a network at any scale. Los Angeles, due to its law requiring helipads for emergency evacuations of tall structures, does have substantial VTOL infrastructure [?]. However, that law was unique to that one particular city and is not indicative of larger trends.

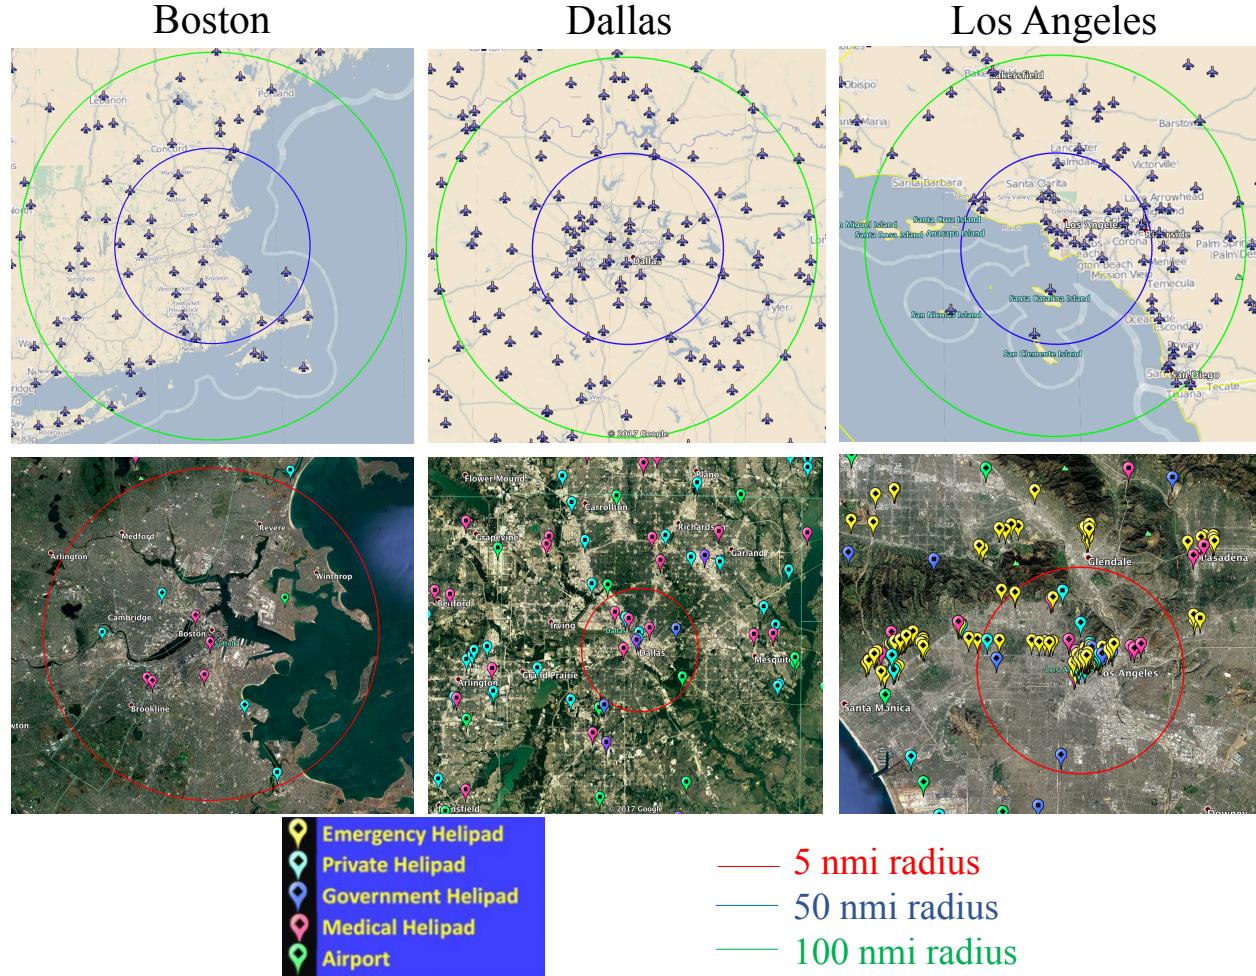

Figure 2: Surface congestion surrounding major metropolitan areas drives the need for urban air transportation

If significant infrastructure investments are required to make the UAM vision a reality, then the feasibility of the STOL UAM concept rests strongly on whether there are sufficient potential locations to build new takeoff and landing areas (TOLAs) in these urban cores. Clearly, whether this is a feasible proposition is strongly dependent on how long of a runway is required. At the scale of conventional commercial aircraft, with required runways lengths in the thousands of feet, it is clearly infeasible to build substantial new infrastructure. On the other end of the spectrum, VTOL aircraft maximize the number of potential infrastructure locations, although noise considerations may prove to be a significant limiting factor. To investigate whether STOL is feasible, an exploration of vehicle design space will be conducted to determine how short of a runway is feasible, while not violating the high-level vehicle requirements. Boston will be used as an example case study to examine the effects of the runway length on feasible infrastructure locations.

III. Vehicle Design Considerations and Key Enabling Technologies

STOL aircraft are not a new concept. The Helio Courier, first built in the late 1940s, is one existing example, with demonstrated takeoff and landing distances of 100-300ft [?]. This performance is achieved through a combination of low wing loading, high power-to-weight, and extensive use of high-lift systems. However, the mechanical systems required are complex, while the low wing loading limits top speed and increases gust sensitivity. Currently, STOL aircraft are not widely adopted outside of the bush pilot community.

The introduction of new electric aircraft technologies have the potential to change the paradigm of current STOL aircraft and make them practical for use in an UAM setting. This is similar to the way these technologies are being proposed to change vertical flight. The following are the key technologies that are considered for an electric STOL (eSTOL) aircraft. For each technology, a baseline and advanced variant will be used, to account for uncertainty in the effectiveness of the technology or potential future advancements.

SHORT TAKEOFF AND LANDING CONSIDERATIONS Figure 3 shows a simplified sketch of the aircraft during takeoff (top) and landing (bottom). At a high level, the runway a vehicle operates off of must be equal to the larger of either the takeoff or landing distances. To shorten the runway, both the takeoff and landing distances S_{TO} and S_{land} must be reduced. The takeoff distance is a function of the time it takes the aircraft to reach a given liftoff speed V_{LO} , which is a multiple (1.3 for this class of vehicles []) of the vehicle stall speed. The stall speed is related to the high-level aircraft parameters by equation 1. To reduce the takeoff distance, the vehicle design can be changed such that it reaches the liftoff speed faster, or the liftoff speed can be lower. To reach the speed faster, thrust can be increased. To reduce the takeoff speed, the stall speed can be decreased either by increasing the CL_{max} parameter or by decreasing the wing loading W/S_{ref} . These changes also serve to increase the climb angle γ_{climb} , which is desirable to minimize the time spent at low altitude. Similarly for .

In both cases, it can be seen that decreasing the wing loading W/S_{ref} and increasing the CL_{max} reduces the stall speed, which to first order decreases both the takeoff and landing distances. That makes these two powerful knobs in the vehicle design space, but they have an effect on the overall vehicle system design. The effect of increasing CL_{max} is an increase in wing system weight and complexity (due to the high-lift system required). These effects at a system level are relatively small, and the maximum CL can only be increased so far. Decreasing the wing loading below its optimal value increases the wing size relative to the rest of the aircraft. This improves low-speed performance but reduces efficiency and increases the power required in cruise, for a given design cruise speed. This additional drag means additional batteries are required, which adds weight and further increases the required wing size.

To further shorten the takeoff distance, thrust can be increased at the cost of additional motor weight; this effect is relatively small as will be shown later, especially for DEP configurations. Landing distance can be decreased by increasing drag after touchdown, either through conventional wheel brakes, aerodynamic braking, reverse thrust, or some combination of all three.

DISTRIBUTED ELECTRIC PROPULSION DEP is a collection of enabling technologies (high specific energy batteries, electric motors) that enable a few large propulsors to be replaced with many smaller ones. The NASA X-57 shown in Figure ?? is an example of a fixed-wing DEP configuration currently being developed. This novel propulsion system architecture allows optimization of different parts of the propulsion system for different phases of flight, which increases overall efficiency. It also increased system redundancy, and most importantly for this application increases the effectiveness of the wing through blown lift. No penalty to cruise efficiency for increased takeoff power. [?]

BLOWN LIFT Blown lift is a increases the effective wing lift coefficient through two main effects. The first is the increase in effective dynamic pressure over the wing due to the accelerated propeller wake. The second is the interaction between the propeller wake and the flaps, which turn the wake downward and produce an upwards force as a result. [?]. Figure ?? is from a NASA investigation into the effectiveness of blown lift. [?] It shows, for an X-57 like wing, that substantial increases in effective wing CL are possible. As a conservative estimate, 4.0 was used as our baseline value of takeoff CL_{max} , and 5.0 for the advanced value. From this figure it should be noted that the power required to achieve the high CL becomes quite high, especially in the landing configuration. As discussed in a paper by Antcliff [?], this presents a challenge when the aircraft is on approach. If the power required to achieve a high lift coefficient for a given vehicle exceeds the power required for a given approach angle (or level flight in the limit), then it is not useful for

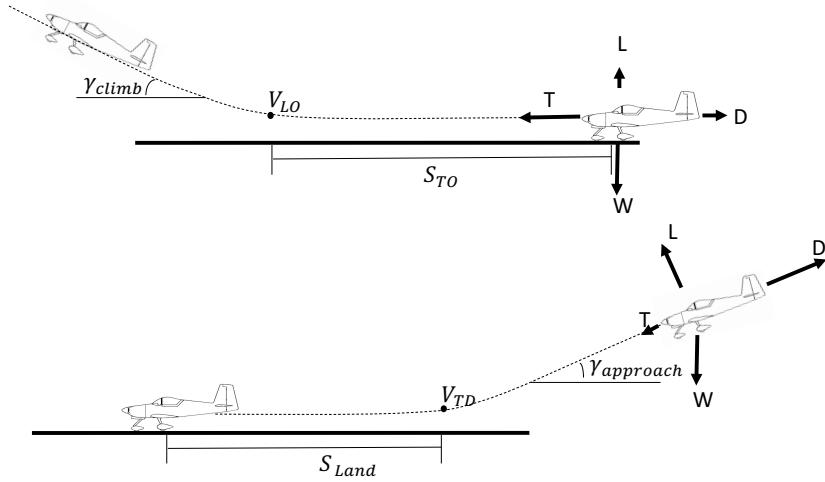

Figure 3: Considerations for short takeoff and landing

landing. This effect may be offset by adding drag (spoilers, windmilling propellers) which would also have the beneficial effect of increasing approach angle, but this becomes a detailed vehicle-level trade study. For the purposes of this paper it is assumed that approach constraints limit the effectiveness of blown wings to 3.5 in the baseline case, and 4.5 in the advanced case.

HIGH POWER ELECTRIC MOTORS Apart from their role as an enabling component of DEP, electric motors have two other useful capabilities for electric aircraft. The first is the ability to be operated at power settings significantly higher than maximum continuous power for short periods of time. Since high power is most important for a short time at takeoff, this effect could significantly minimize the weight penalty of a high-power propulsion system. Additionally, the rotation direction of these motors can be electrically reversed. This is useful on braking to provide reverse thrust/massive drag at touchdown, which shortens landing distance without the weight penalty of dedicated thrust reversal systems.

ADVANCED FLIGHT CONTROLS Advances in flight control development allow precise control of vehicles on landing approach, and control of vehicles at or past stall through the use of dynamic maneuvers.

IV. Vehicle Feasibility

A sizing study using Geometric Programming optimization was performed to understand how vehicle performance and design would be effected by short take offs and landings. This section describes the assumptions and equations used in the optimization model for vehicle size, cruise performance, and takeoff and landing distances.

Geometric programming was selected as a means of evaluating this trade space because of its speed and reliability. Geometric programming is a special type of convex, non-linear optimization.[?] Because it is convex, even GPs with thousands of variables can be solved quickly.[?] Additionally, recent research has shown that GPs can be used to evaluate aircraft design trade spaces.[?][?]

Table 1: Add caption

	Baseline	Advanced
D.E.P.	No loss of efficiency at cruise	No loss of efficiency at cruise
Blown Lift	Clmax Takeoff: 4.0 Clmax Land: 3.5	Clmax Takeoff: 5.0 Clmax Land: 4.5
Electric Motor	No additional power at takeoff	20% additional power at takeoff Reverse thrust on landing
Advanced flight controls	Current required margins on stall speed and runway	Reduction in required speed and runway margin

A. Vehicle Model

It is assumed that the aircraft is completely electric, relying on battery power for powered flight. The aircraft weight is comprised of the battery, payload, wing, motor, and structural weight,

$$W_{MTO} \geq W_{batt} + N_{pax}W_{pax} + W_{wing} + W_{motor} + W_{struct} \quad (1)$$

where the motor, passenger, and structural weights are

$$W_{motor} \geq \frac{P_{shaft_max}}{P_{spec}} \quad (2)$$

$$W_{pax} = 195[\text{lbf}] \quad (3)$$

$$W_{struct} \geq W_{MTO}f_{struct}. \quad (4)$$

The battery weight is constrained by the range of the aircraft

$$R \leq \frac{h_{batt}W_{batt}\eta_{elec}V}{gP_{shaft}} \quad (5)$$

where the shaft power is

$$P_{shaft} \geq \frac{TV}{\eta_{prop}} \quad (6)$$

The aircraft is assumed to be in steady level flight during cruise.

The wing weight is composed of the skin, main spar and additional components

$$W_{wing} \geq W_{skin} + W_{spar} + W_{fadd} \quad (7)$$

The skin and structural elements are assumed to be carbon fiber. The wing spar configuration is a cap spar with unidirectional carbon fiber caps wrapped in a shear web as shown in Figure 4.

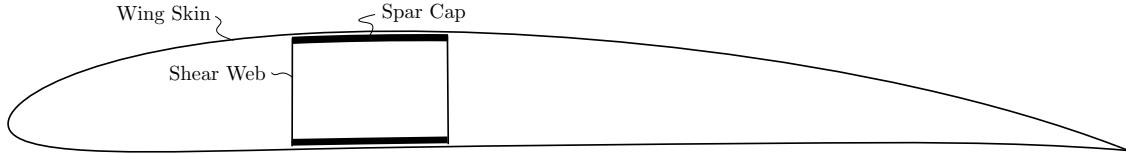

Figure 4: Cross sectional view of a cap spar.

The spar dimensions are sized such that the material stresses are not exceeded under a 3.5 g-load,

$$\sigma_{CFRP} \geq \frac{\mathcal{M}_{root}}{S_{y_{spar}}} \quad (8)$$

The root wing moment \mathcal{M}_{root} , is calculated assuming a distributed load along the wing span that scales with the local chord.[?] A constant tapered wing is assumed. This wing sizing model leverages the GP wing sizing model used by Burton and Hoburg.[?]

A simple drag model is used for the aircraft,

$$C_D \geq CDA + c_{d_p} + \frac{C_L^2}{\pi e AR}. \quad (9)$$

where the profile drag coefficient $c_{d_p}(C_L, Re)$, is calculated from a representative wing polar. The combined drag and wing loading models allow the aspect ratio to be optimized, trading structural integrity with aerodynamic performance.

B. Takeoff and Landing Models

The takeoff model was adapted from Raymer's takeoff equations to fit a GP compatible form. Using equations of motion the takeoff state can be expressed

$$T - D - \mu(W_{MTO} - L) = \frac{W_{MTO}}{g} \frac{dV}{dt}. \quad (10)$$

This can be simplified to

$$\frac{dV}{dt} = g \left(\frac{T}{W_{MTO}} - \mu \right) - \frac{g}{W_{MTO}} \left(\frac{1}{2} \rho S V^2 (C_{D_g} - \mu C_{L_g}) \right) \quad (11)$$

$$\frac{dt}{dV} = \frac{1}{A - BV^2} \quad (12)$$

The takeoff ground run distance can then be expressed by taking the integral of Equation 12 to achieve

$$S_{TO} = \frac{1}{2B} \ln \frac{A}{A - BV^2} \quad (13)$$

The natural log function can be approximated to make Equation 13 GP-comptible by

$$\ln \frac{A}{A - BV^2} \approx 5.6 \times 10^{-4} A^{-6.04} (BV^2)^{6.04} + 1.0 A^{-0.001} (BV^2)^{0.001} + 7.5 \times 10^{-4} A^{-1.276} (BV^2)^{1.275} \quad (14)$$

with an average log error of 0.06%. The terms A , and B , are constrained by

$$\frac{T}{W_{MTO}} \geq \frac{A}{g} + \mu \quad (15)$$

$$B \geq \frac{g}{W_{MTO}} \frac{1}{2} \rho S C_{D_g} \quad (16)$$

where the μC_{L_g} term is neglected as a conservative approximation for B to preserve GP-compatibility.

The landing ground roll distance is calculated using conservation of energy, with the primary design variable being the loading deceleration factor, N . This constraint will drive the wing loading down.

$$S_{land} \geq \frac{1}{2} \frac{V^2}{Ng} \quad (17)$$

where $N = 1$ corresponds to a 1-g deceleration. The deceleration factor is a function of the technologies used to stop the aircraft and include, but are not limited to: breaks, reverse thrust from electric motors, and drag. To understand how the g-loading constant varies with different amounts of reverse thrust, the ground roll and deceleration factor are calculate for the X-57 as an example case. Table 2 shows the deceleration loading factor for different amounts of reverse thrust.

Table 2: Landing Case for the X-57

	Ground Roll Distance	Deceleration Factor (N)
Brakes only (dry)	925 [ft]	0.37
Brakes + 10% reverse thrust	850 [ft]	0.4
Brakes + 50% reverse thrust	625 [ft]	0.55
Brakes + 100% reverse thrust	425 [ft]	0.73

For both the landing and takeoff constraints it is assumed that the velocity has a 20% margin on the stall velocity,

$$V = 1.2V_{\text{stall}} = \sqrt{\frac{2W_{\text{MTO}}}{\rho SC_{L_{\max}}}}. \quad (18)$$

It is assumed that the the max lift coefficient is different for landing and takeoff. Another 40% margin is placed on the ground roll distance to determine runway length

$$S_{\text{runway}} \geq 1.4S_{\text{TO}} \quad (19)$$

$$S_{\text{runway}} \geq 1.4S_{\text{land}} \quad (20)$$

C. Vehicle Trade Studies

Using the geometric programming model of a STOL aircraft perviously described, tradeoffs between runway length and vehicle performance were evaluated. The models consists of a 105 free variables and was solved in 0.114 seconds with an objective function to minimize weight, $\min(W_{\text{MTO}})$. Key parameters are defined in Table 3 and important solution variables are shown in Table 4.

Table 3: Design Parameters

Parameter	Value
S_{runway}	300 [ft]
η_{elec}	0.9
h_{batt}	210 [Whr/kg]
P_{spec}	0.7136 [kW/N]
R	100 [nmi]
V_{\min}	100 [kts]
$C_{L_{\max}}$ (Landing)	3.5
$C_{L_{\max}}$ (TO)	4.0
N	0.3g
η_{prop}	0.8

Table 4: Design Variables

Parameter	Value
W_{MTO}	1496 [lbf]
W_{batt}	278 [lbf]
W_{wing}	53 [lbf]
AR	9
b	22.3 [ft]
V_{stall}	48 [kts]
(W/S)	27 [lbf/ft ²]

To understand how passenger and runway requirements affect vehicle weight, the GP model was solved 30 times in 3.46 seconds. The results are shown in Figure 5(a), each point on the graph corresponding to a unique optimization solution or vehicle size. From this study it is observed that for runway lengths shorter than 250 ft are near infeasible for this set of parameters. It is also oberserved that the runway length is fairly insensitive to number of passengers.

By looking at the sensitivity to the lift coefficient, shown in figure 5(b), on landing for the same trade study shown in figure 5(a), it can be determined whether the aircraft is constrained by the landing constraints or the take off constraints. The sensitivity to a variable in a geometric program is defined as the percentage

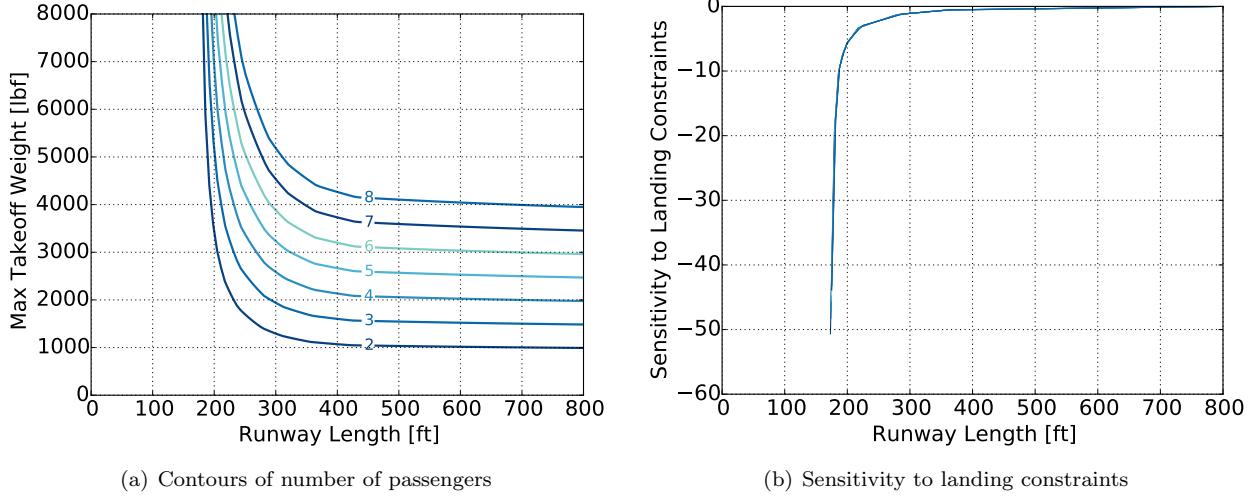

Figure 5: Trade space of aircraft weight, number of passengers and runway length.

change in the objective function for a 1% change in that variable's value. For this study, either the landing constraints or the take off constraints will be active or driving the size of the vehicle. Thus, if the sensitivity to the lift coefficient on landing is zero, then the landing constraints are not active. Conversely, if the sensitivity is non-zero then those constraints are active and the vehicle size is landing constrained.

Another way to view this trade space is to understand how runway length and range are effected by different minimum speed requirements. Figure ?? shows plots of minimum cruise speed vs max take off weight for different contours of runway length and range requirements. This trade study was done for 5 passengers. These plots show that short runway and longer range requirements are possible but require slower cruise speeds. Because power scales with velocity cubed, slower speed reduces the required power and therefore battery weight, which improves the whole system. Note that in both plots shown in figure ??, lowering the minimum speed does not always improve the vehicle weight. A flat curve indicates that the aircraft is not constrained by the minimum cruise speed because of the optimum cruise speed for that set of requirements is faster than the minimum cruise speed.

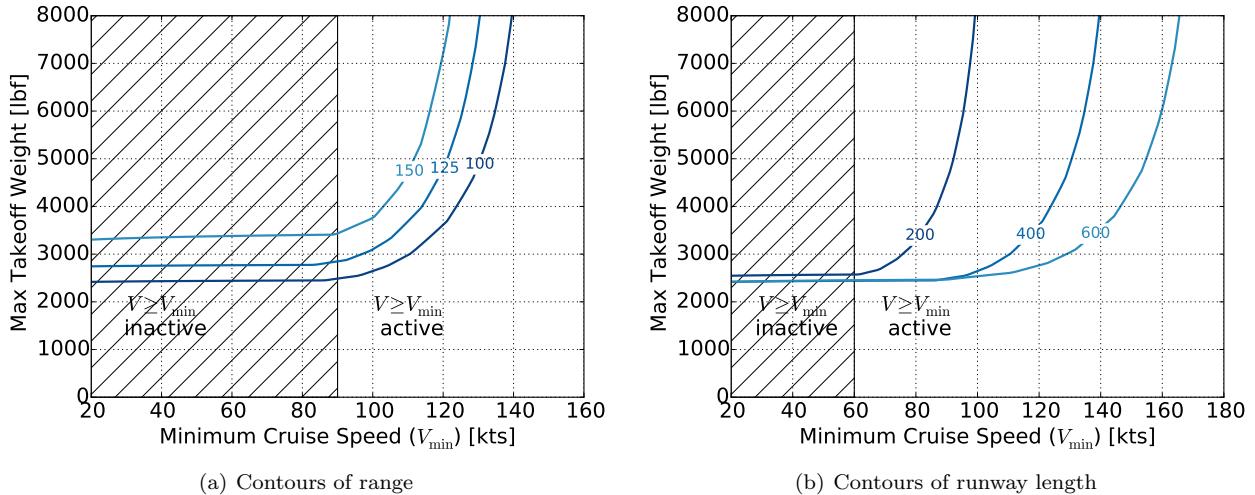

Figure 6: Trade study between requirements of runway length, minimum speed and range.

D. Advanced Technology Trade Studies

The previous section showed fundamental trade studies and trends for how runway length varies with performance. It is also possible to shorten runway length through advanced technology. As discussed previously, a number of technologies could help reduce the required runway length including power bursts from electric motors, reverse thrust on landing, advanced flight controls, and improved battery technology. The effect of these technology advances on required runway length can be observed by changing a few parameters from the baseline case and resolving the optimization model. Table 5 compares the baseline parameters to the advanced technology parameters that were assumed in the optimization model.

Table 5: Advanced Technology Parameter Assumptions

Parameter	Baseline Value	Advanced Value
h_{batt}	210 [Whr/kg]	300 [Whr/kg]
P_{spec}	0.7136 [kW/N]	0.571 [kW/N]
$C_{L_{\max}} \text{ (Landing)}$	3.5	4.5
$C_{L_{\max}} \text{ (TO)}$	4.0	5.0
N	0.3	0.5
Runway margin	40%	20%
Stall speed margin	30%	10%

The motor power to weight ratio was lowered to take credit for the electric motor power burst during take off and is 80% of the baseline value. The maximum lift coefficient during landing and takeoff were increased to match values predicted by NASA. The landing deceleration factor was increased to take credit for use of reverse thrust on landing. The lower margins on the runway length and stall speed are assuming advanced flight controls that require less margin. Realistically achieving all of these advances in a STOL aircraft design is unlikely. However, understanding the extremes between the baseline, conservative case and a more optimistic case is useful in determining a feasible vehicle design and vehicle requirements. Figure 7 shows the same trade study as figure 5, but with the updated parameter values shown in Table 5.

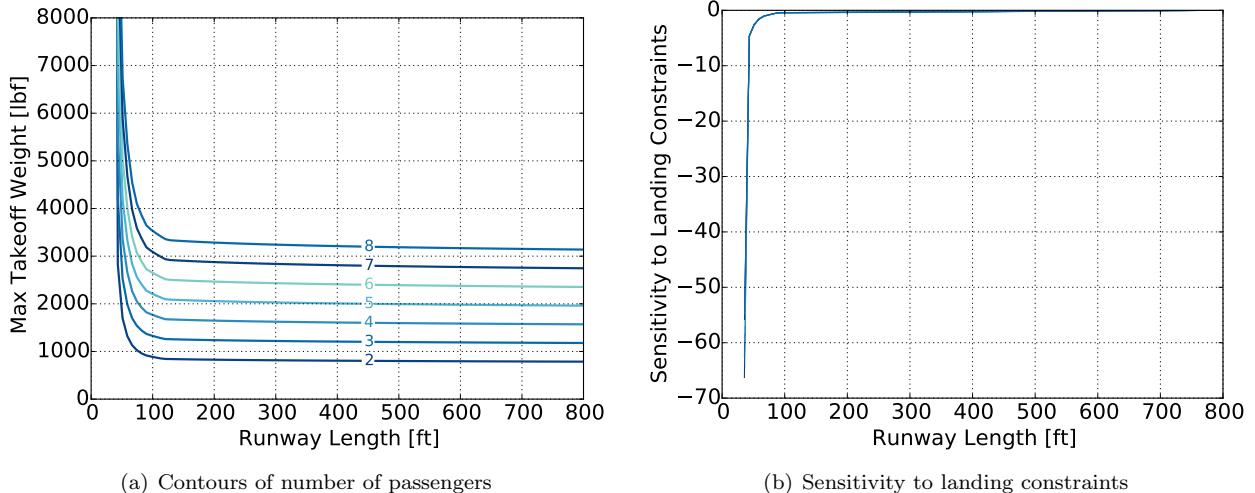

Figure 7: Trade space of aircraft weight, number of passengers and runway length for advanced technology assumptions.

As observed in figure 7(a), the advanced technology assumptions allow for a much shorter runway than the baseline case showing that runways below even 100 ft might be possible. To understand which parameters have the largest effect on this trade study, each parameter can be varied one at a time from the baseline case. Figure 8 show variations on the 5 passenger contour from figure 5(a).

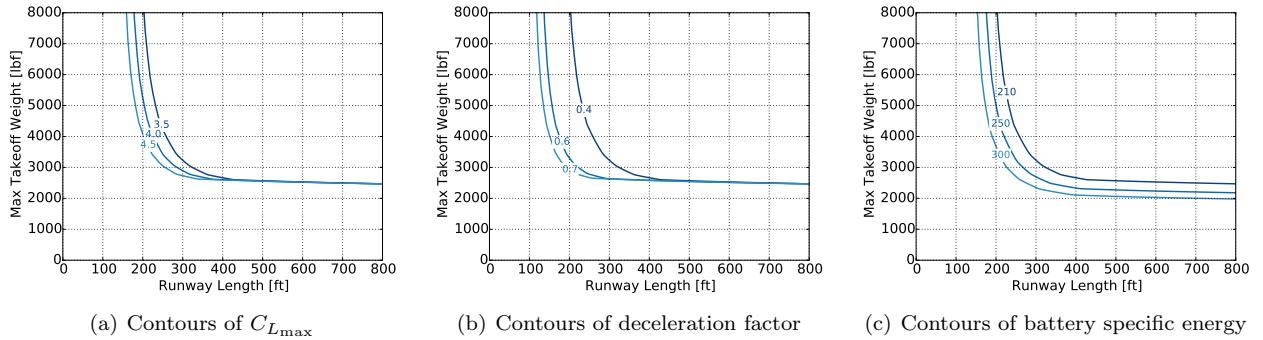

Figure 8: Trade space of aircraft weight, number of passengers and runway length for advanced technology assumptions.

Note that increasing the maximum lift coefficient or the deceleration factor has no effect for higher runway lengths. This is because at higher runway lengths the size of the aircraft is constrained by the range requirement but not the runway requirement. Increasing the battery specific energy however, is always beneficial because that lowers the battery weight which improves the whole system.

V. Infrastructure Feasibility

Infrastructure is another aspect of the system that drives the vehicle design. A range of feasible runway lengths is a requirement that flows from infrastructure and in turn defines what vehicle designs are also feasible. As previously discussed, there is a substantial amount of airport infrastructure located outside of urban centers; however within an urban center, much less airport or runway infrastructure exists. Therefore this infrastructure study will specifically consider feasible infrastructure within an urban center. The city of Boston will be used for this case study. Key topics to address include what considerations drive the placement of STOLports, what are feasible location types, and how does infrastructure availability change with infrastructure type and required size. The goal in selecting locations for STOLport infrastructure is to be able to connect to existing transportation infrastructure within an urban center.

SITE CONSIDERATIONS Site considerations are not driven solely by runway length. The minimum rectangular area upon which a STOLport can be built is defined by runway length as well as room for taxiways, clearway requirements, and space for parking and charging stations. Clearway requirements are written in the FAA AC 150/5300 and are dependent on aircraft size and speed [1??]. For locations that may be space restricted, a STOLpad rather than a STOLport concept is possible, which would consist of only the bare minimum infrastructure and would not include space for considerations such as parking and charging stations. Site considerations are also dependent on VFR approach and departure paths and the need for obstacle avoidance. Obstacle avoidance is defined as a plane of a defined width at a given distance and height from the runway, through which no obstacle may protrude; obstacle avoidance definitions are also dependent on vehicle size and speed [1??]. The key drivers for site considerations are area available, which is more than solely runway length, and obstacle avoidance for approach and departure paths.

CROSSWING MITIGATION An additional consideration for infrastructure availability is crosswind mitigation. In order to have a robust UAM system, wind should not be a prohibitive factor for operations. Specific considerations for the particular wind patterns of the city in question should be incorporated when deciding on infrastructure location. There are various techniques to mitigate for multiple wind directions. One way is to have conventional crosswind runways. A disadvantage for this is that it will require additional surface area for the STOLport, which could possibly reduce the amount of infrastructure available. To reduce the severity of this impact, the crosswind design could take credit for the headwind component inherent in triggering the switch to the crosswind runway. A rule of thumb says that take-off and landing distances are reduced by 1.5 % for each knot of headwind up to 20 knots [experimentalaircraft.info reference]. An additional option would be to create a circular STOLport with the diameter of the required runway length. The runway heading could be set dynamically based on the prevailing winds. This would require more complex approach and

departure procedures, 360-degree obstacle clearance, and portable charging stations. If the STOLport is built over linear pre-existing infrastructure such as highways and railways, an additional STOLport can be built nearby with a perpendicular orientation to serve the same geographic location when crosswind conditions exist. Lastly, if barges are used as the STOLport then they could be moored to allow for rotation into the wind. This would require an increased footprint in the waterways which needs to be deconflicted with boating channels. In addition to infrastructure design, the eSTOL vehicle design could also be used to mitigate crosswind landings. A larger vertical stabilizer or increased control surface could increase the safe crosswind strength on landing. The design could also incorporate specific adjustments to the landing gear to facilitate higher crosswind landings, such as rotating landing gear, which would allow the nose of the aircraft to remain into the wind all the way through touchdown. One additional design consideration would be to introduce advance controls or maneuvers to allow for safe crosswind landings. With advances happening rapidly with high-precision approach and landing guidance, crosswind landings can be mitigated through automation.

FEASIBLE LOCATIONS A network of notional sites within Boston was designed with the previous considerations in mind. The network of notional sites is shown in Figure 9. Within the network there are four types of possible STOLport locations, which are also shown in Figure 9. The four types of locations to place a STOLport are on top of a building, over a highway or railway, on a barge over a body of water, or on the ground. Visualizations for the four types of STOLport locations are shown in Figure 10. The barge location shows a runway and possible space for charging stations. The highway or railway location shows a runway on an elevated structure, with a ramp for the aircraft to taxi down to a lower level with charging stations. The building location shows the possibility for crosswind runways depending on the area available, and space for charging stations are also shown. The ground location is similar to the building location with crosswind runways depending on the area available and charging stations again shown. The network of notional sites identified accounting for previously discussed considerations included building locations, highway or railway locations, barge locations, and ground locations.

SCALING Buildings are the type of infrastructure location that is most dependent on runway length. Considerations for scaling an infrastructure network do vary between the types of locations. At highway and railway locations, placing any length of runway is fairly easy because the length of highways and railways far exceeds the length of STOLport runways. For highways and railways, possible scaling challenges include the fact that highway and railway infrastructure is limited in downtown areas due to tunnels. For barges, many

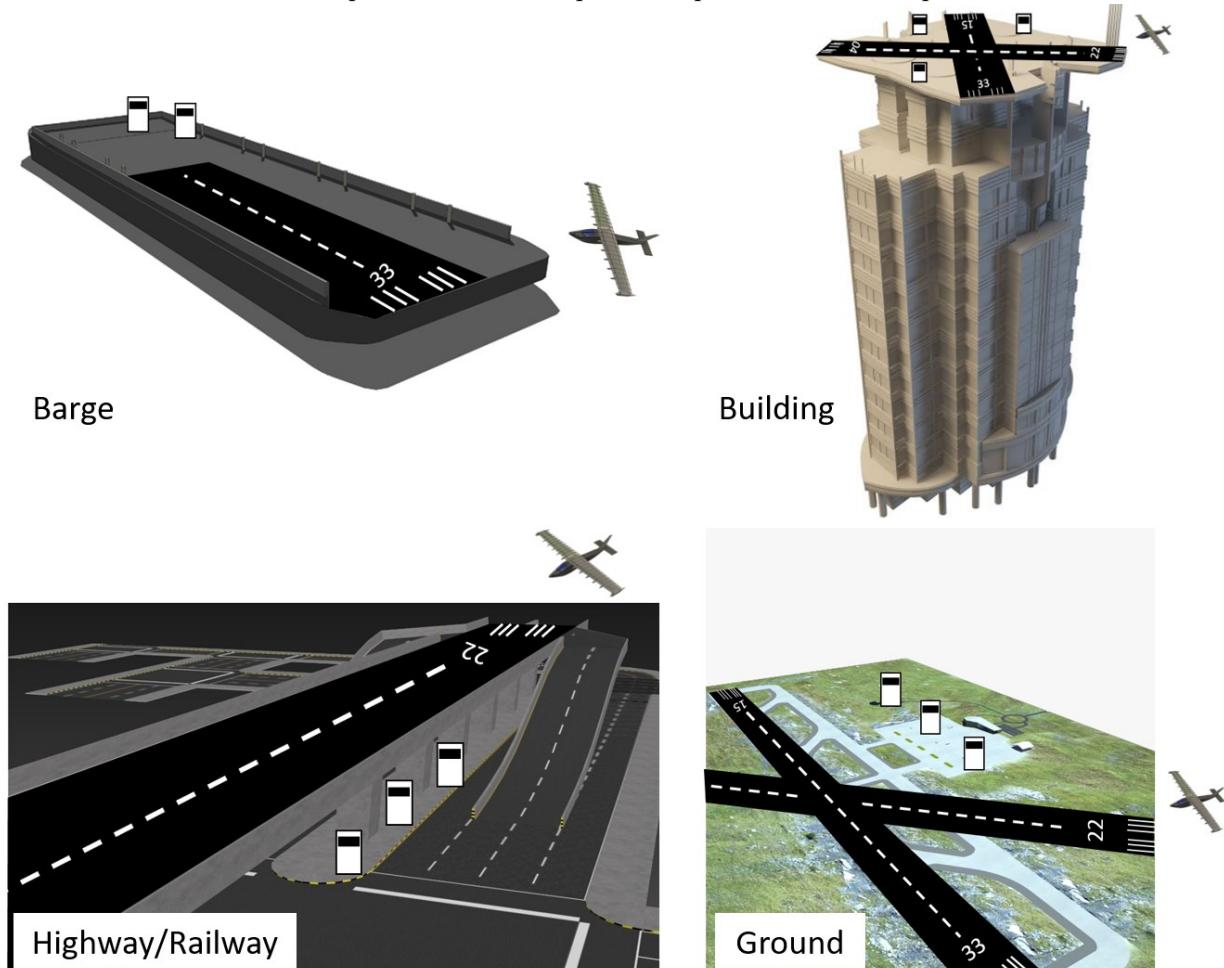

Figure 10: STOLport placement options

major cities are located by large bodies of water which allows for much available area in order to scale the number of barge locations. However barges must consider ways to connect to the shore and avoiding shipping lanes. Scaling a network of ground infrastructure locations is not really feasible in an urban center aside from already existing airports. Buildings are generally widely available within an urban center, however buildings will require shorter runway lengths compared to the other locations because of limited rooftop area. Building STOLport locations are the type of location that is most dependent on runway length. GIS building footprint data was analyzed in order to understand how building infrastructure varies with runway length. Again, buildings are the type of STOLport location most dependent on runway length, as discussed in the previous paragraph. GIS data provides the footprints of buildings in a city [2,3]. Based on this GIS data, if at least one side of the building footprint was as long as a given runway length, then the footprint was counted as a possible building. Figure 11 shows heat maps created using the building footprint GIS data for Boston and Los Angeles. The heat maps show that the possible buildings for different runway lengths are distributed throughout the city making it possible to scale an infrastructure network that is not all concentrated at one location. Using the same method of counting possible buildings from the GIS building footprint data, Figure 12 shows data trends of possible buildings as a function of runway length in order to provide insight into the manner in which the number of available buildings varies with runway length. For runway lengths of 400-600 feet, the number of possible buildings does allow for designing a network STOLport locations to be feasible. Runway lengths of 300 feet or less allow for a significant increase in the number of possible building locations for STOLports. The trend is that as runway length decreases, the number of possible buildings for STOLports exponentially increases.

VI. Key Challenges and Risks

- Crosswind
- Passenger comfort, gust rejection
- Effectiveness of reverse thrust, blown lift
- Noise
- Ground overflight

VII. Conclusion

INFRASTRUCTURE Possible types of locations for STOLports identified in this study include on top of buildings, over highways and railways, on barges, or on the ground of existing airports. Building infrastructure is the type of location most dependent on runway length. The STOLport locations can support runway lengths of 400 to 600 feet. If a vehicle is able to land in a runway of 300 feet or less, then the number of possible STOLport locations exponentially increases. Landing in a runway length of 500 feet or less could allow for novel operations at existing major airports. The results of the infrastructure study indicate that it is possible to design a STOLport network in an urban center.
